Software Technology Colloquium
February 25, 2010

About this work

- ▶ Paper to be presented at the Workshop on Language Descriptions, Tools, and Applications (**LDTA 2010**), Paphos, Cyprus, March 27–28, 2010.
- ▶ Two-day satellite event of the European Joint Conferences on Theory and Practice of Software (**ETAPS 2010**): “primary European forum for academic and industrial researchers working on topics relating to software science”.

Type-driven program transformation

Typically proceeds in two logical phases:

- ▶ **Analysis:** annotating a source program with types from a nonstandard type system capable of expressing certain properties of interest.
- ▶ **Synthesis:** using the annotations to drive the actual transformation into a target program.

Often establishes some form of program optimisation.

Dead-code elimination

doesn't use its 2nd argument

```
const ::  $\forall \alpha \beta. \alpha \rightarrow \beta \rightarrow \alpha$   
const x y = x
```

```
goldenRatio :: Double
```

```
goldenRatio =
```

```
const 1.618 (( $\lambda z \rightarrow z^2 + 2 * z + \frac{(z+3) * (z+2)}{(z+1)^2}$ ) 3.141) \perp
```

live code

dead code

☞ Transformation must be **safe**, i.e., semantics-preserving.

Type-driven DCE

Analysis: annotate the program with **liveness types**.

- ▶ **D** for code that is *guaranteed not to be evaluated*.
- ▶ **L** for code that *may be evaluated*.
- ▶ $\cdot \rightarrow \cdot$ for *functions*.

Synthesis: replace code with type **D** by \perp .

Type-driven DCE: example

$::L \rightarrow D \rightarrow L$

```
const ::  $\forall \alpha \beta. \alpha \rightarrow \beta \rightarrow \alpha$   
const x y = x
```

$::L$

$::L$

```
goldenRatio :: Double  
goldenRatio =
```

```
const 1.618 (( $\lambda z \rightarrow z^2 + 2 * z + \frac{(z+3)*(z+2)}{(z+1)^2}$ ) 3.141)
```

$::L \rightarrow D \rightarrow L$

$::L$

$::D$

Subeffecting

- ▶ It is safe to silently “cast” an expression of type L to type D .
- ▶ In particular: live arguments can be bound to dead parameters.

$$f\ x = \text{const}\ x\ x$$

- ▶ Akin to subtyping in object-oriented languages.

Subeffecting: example

$::(D \rightarrow L) \rightarrow D \rightarrow L$

$::L::$ (Subeffecting)

$twice :: \forall \alpha. (\alpha \rightarrow \alpha) \rightarrow \alpha \rightarrow \alpha$
 $twice f x = f (f x)$

$::L$

$::D \rightarrow L$

$::D \rightarrow L$ $::D$

$goldenRatio :: Double$

$goldenRatio =$

$twice (\lambda y \rightarrow 1.618) ((\lambda z \rightarrow z^2 + 2 * z + \frac{(z+3)*(z+2)}{(z+1)^2}) 3.141)$

$::D \rightarrow L$

$::D$

$::(D \rightarrow L) \rightarrow D \rightarrow L$

Another HOF example

$::(L \rightarrow L) \rightarrow L \rightarrow L$

$::L$

$twice :: \forall \alpha. (\alpha \rightarrow \alpha) \rightarrow \alpha \rightarrow \alpha$
 $twice f x = f (f x)$

$::L$

$::L \rightarrow L$

$::L \rightarrow L$

$::L$

$goldenRatio :: Double$

$goldenRatio = twice (\lambda y \rightarrow y) 1.618$

$::L \rightarrow L$

$::L$

$::(L \rightarrow L) \rightarrow L \rightarrow L$

Modularity

What liveness type to assign to an HOF depends on how it's used.

$$\text{twice } (\lambda y \rightarrow 1.618) ((\lambda z \rightarrow z^2 + 2 * z + \frac{(z+3)*(z+2)}{(z+1)^2}) 3.141)$$

gives $\text{twice} :: (\mathbf{D} \rightarrow \mathbf{L}) \rightarrow \mathbf{D} \rightarrow \mathbf{L}$.

$$\text{twice } (\lambda y \rightarrow y) 1.618$$

gives $\text{twice} :: (\mathbf{L} \rightarrow \mathbf{L}) \rightarrow \mathbf{L} \rightarrow \mathbf{L}$.

But what if we require **separate compilation**?

☞ The uses of an exported function may not be known at compile-time.

Assume that parameters of function type are to be bound to functions that may use all their arguments.

For example:

$$twice :: (L \rightarrow L) \rightarrow L \rightarrow L$$

☞ This is always safe, but pessimism typically propagates to use sites.

Pessimisation: example

$::(L \rightarrow L) \rightarrow L \rightarrow L$

$twice :: \forall \alpha. (\alpha \rightarrow \alpha) \rightarrow \alpha \rightarrow \alpha$
 $twice f x = f (f x)$

$::L$

$goldenRatio :: Double$
 $goldenRatio =$

$twice (\lambda y \rightarrow 1.618) ((\lambda z \rightarrow z^2 + 2 * z + \frac{(z+3)*(z+2)}{(z+1)^2}) 3.141)$

remains :-(
 $(z+3)*(z+2)$

$::L \rightarrow L$

$::(L \rightarrow L) \rightarrow L \rightarrow L$

Polyvariance

Allow liveness types to abstract over liveness properties.

That is, use polymorphic types as in ML or Haskell:

```
twice ::  $\forall \beta. (\beta \rightarrow L) \rightarrow \beta \rightarrow L$ 
```

☞ Resulting transformation is **polyvariant** or **context-sensitive**.

Polyvariance: example

$::\forall\beta. (\beta \rightarrow L) \rightarrow \beta \rightarrow L$

still transformed pessimistically

$twice :: \forall\alpha. (\alpha \rightarrow \alpha) \rightarrow \alpha \rightarrow \alpha$
 $twice f x = f (f x)$

$::L$

$goldenRatio :: Double$
 $goldenRatio =$

$twice (\lambda y \rightarrow 1.618) ((\lambda z \rightarrow z^2 + 2 * z + \frac{(z+3)*(z+2)}{(z+1)^2}) 3.141)$

$::D \rightarrow L$

$::D$

$::(D \rightarrow L) \rightarrow D \rightarrow L$ (instantiation)

Implementation

Type systems provide useful idioms for designing and defining analyses and transformations: subeffecting, polymorphism, . . .

What about implementing type-driven transformations?

It seems natural to adapt an off-the-shelf type-inference algorithm for Haskell-like languages.

But. . .

Principal types

Standard type-inference algorithms associate functions with their most polymorphic type.

For example:

$$\text{twice} :: \forall \beta_1 \beta_2 \beta_3 \beta_4. (\beta_1 \rightarrow \beta_1 \sqcup \beta_2 \sqcup \beta_3) \rightarrow \beta_1 \sqcup \beta_4 \rightarrow \beta_2$$

$$\varphi_1 \sqcup \varphi_2 = \begin{cases} D, & \text{if } \varphi_1 = \varphi_2 = D \\ L, & \text{otherwise} \end{cases}$$

- 👉 Principal types guarantee the highest degree of context-sensitivity.

Local functions

```
goldenRatio =  
  let  
    twice f x = f (f x)  
  in  
    twice ( $\lambda y \rightarrow 1.618$ )  
      ( $(\lambda z \rightarrow z^2 + 2 * z + \frac{(z+3)*(z+2)}{(z+1)^2}) 3.141$ )
```

- ▶ Assigning *twice* its principal type means that the body of *twice* is transformed pessimistically.
- ▶ Assigning *twice* the monomorphic type $(D \rightarrow L) \rightarrow D \rightarrow L$ means that we eliminate the subexpression $(f x)$ from the body of *twice*.

Local functions (cont'd)

So, should local functions always have monomorphic types?

```
goldenRatio =  
  let  
    twice f x = f (f x)  
  in  
    twice ( $\lambda y \rightarrow 1.000$ ) 3.141 + twice ( $\lambda z \rightarrow z$ ) 0.618
```

- ☞ The only safe monomorphic type for *twice* is $(L \rightarrow L) \rightarrow L \rightarrow L$, which prevents the elimination of 3.141.
- ☞ **Poisoning**: a **single** use with a “bad” type spreads to **all** use sites.

Strategy for higher-order functions

- ▶ If a closed-scope HOF is **only applied to dead arguments**, annotate the corresponding parameter with **D**. (Body can be optimised aggressively.)
- ▶ If a closed-scope HOF is **only applied to live arguments**, annotate the corresponding parameter with **L**. (Nothing can be gained from annotating it polymorphically.)
- ▶ If a closed-scope HOF may be **applied to both dead and live arguments**, annotate the corresponding parameter polymorphically. (Avoids poisoning.)

Open-scope HOFs are always assigned their principal types.
(Ensures highest degree of safety and flexibility.)

A typing derivation for a given expression is **minimal** if no other typing derivation for the same expression would avoid type abstractions where the derivation under consideration could not.

- ☞ Type-driven polyvariant program transformations are best implemented with algorithms that compute MTDs rather than standard algorithms such as Algorithm W.

Conclusions

- ▶ Polymorphism: balancing modularity and precision.
- ▶ Minimal typing derivations: preventing pessimisation at definition sites of local functions.
- ▶ Some degree of flexibility in what constitutes a module.
